Abstract

We present a framework that abstracts Reinforcement Learning (RL) as a sequence modeling problem. This allows us to draw upon the simplicity and scalability of the Transformer architecture, and associated advances in language modeling such as GPT-x and BERT. In particular, we present Decision Transformer, an architecture that casts the problem of RL as conditional sequence modeling. Unlike prior approaches to RL that fit value functions or compute policy gradients, Decision Transformer simply outputs the optimal actions by leveraging a causally masked Transformer. By conditioning an autoregressive model on the desired return (reward), past states, and actions, our Decision Transformer model can generate future actions that achieve the desired return. Despite the simplicity, Decision Transformer matches or exceeds the performance of state-of-the-art model-free offline RL baselines on Atari, OpenAI Gym, and Key-to-Door tasks.

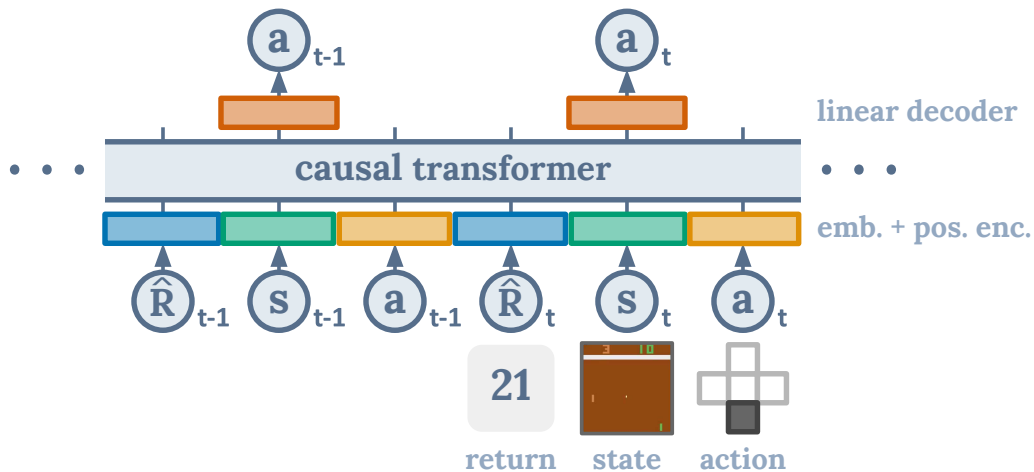

Figure 1: Decision Transformer architecture¹. States, actions, and returns are fed into modality-specific linear embeddings and a positional episodic timestep encoding is added. Tokens are fed into a GPT architecture which predicts actions autoregressively using a causal self-attention mask.

¹Our code is available at: <https://sites.google.com/berkeley.edu/decision-transformer>

Atari [10], OpenAI Gym [11], and Key-to-Door [12] environments. We show that – *without using dynamic programming* – Decision Transformer matches or exceeds the performance of state-of-the-art model-free offline RL algorithms [13, 14]. Furthermore, in tasks where long-term credit assignment is required, Decision Transformer capably outperforms the RL baselines. With this work, we aim to bridge sequence modeling and transformers with RL, and hope that sequence modeling serves as a strong algorithmic paradigm for RL.

2 Preliminaries

2.1 Offline reinforcement learning

We consider learning in a Markov decision process (MDP) described by the tuple $(\mathcal{S}, \mathcal{A}, P, \mathcal{R})$. The MDP tuple consists of states $s \in \mathcal{S}$, actions $a \in \mathcal{A}$, transition dynamics $P(s'|s, a)$, and a reward function $r = \mathcal{R}(s, a)$. We use s_t , a_t , and $r_t = \mathcal{R}(s_t, a_t)$ to denote the state, action, and reward at timestep t , respectively. A trajectory is made up of a sequence of states, actions, and rewards: $\tau = (s_0, a_0, r_0, s_1, a_1, r_1, \dots, s_T, a_T, r_T)$. The return of a trajectory at timestep t , $R_t = \sum_{t'=t}^T r_{t'}$, is the sum of future rewards from that timestep. The goal in reinforcement learning is to learn a policy which maximizes the expected return $\mathbb{E} \left[\sum_{t=1}^T r_t \right]$ in an MDP. In offline reinforcement learning, instead of obtaining data via environment interactions, we only have access to some fixed limited dataset consisting of trajectories from the environment. This setting is harder as it removes the ability for agents to explore the environment and collect additional feedback.

2.2 Transformers

Transformers were proposed by Vaswani et al. [1] as an architecture to efficiently model sequences. They consist of stacked self-attention layers with residual connections. Each self-attention layer receives n embeddings $\{x_i\}_{i=1}^n$ corresponding to unique input tokens, and outputs n embeddings $\{z_i\}_{i=1}^n$, preserving the input dimensions. The i -th token is mapped via linear transformations to a key k_i , query q_i , and value v_i . The i -th output of the self-attention layer is given by weighting the values v_j by the normalized dot product between the query q_i and other keys k_j :

$$z_i = \sum_{j=1}^n \text{softmax}(\{\langle q_i, k_{j'} \rangle\}_{j'=1}^n)_j \cdot v_j. \quad (1)$$

This allows the layer to assign “credit” by implicitly forming state-return associations via similarity of the query and key vectors (maximizing the dot product). In this work, we use the GPT architecture [9], which modifies the transformer architecture with a causal self-attention mask to enable autoregressive generation, replacing the summation/softmax over the n tokens with only the previous tokens in the sequence ($j \in [1, i]$). We defer the other architecture details to the original papers.

3 Method

In this section, we present Decision Transformer, which models trajectories autoregressively with minimal modification to the transformer architecture, as summarized in Figure 1 and Algorithm 1.

Trajectory representation. The key desiderata in our choice of trajectory representation are (a) it should enable transformers to learn meaningful patterns and (b) we should be able to conditionally generate actions at test time. It is nontrivial to model rewards since we would like the model to generate actions based on *future* desired returns, rather than past rewards. As a result, instead of modeling the rewards directly, we model the returns-to-go $\hat{R}_t = \sum_{t'=t}^T r_{t'}$. This leads to the following trajectory representation which is amenable to autoregressive training and generation:

$$\tau = \left(\hat{R}_1, s_1, a_1, \hat{R}_2, s_2, a_2, \dots, \hat{R}_T, s_T, a_T \right). \quad (2)$$

At test time, we can specify the desired performance (e.g. 1 for success or 0 for failure), as well as the environment starting state, to initialize generation. After executing the generated action, we decrement the target return by the achieved reward and repeat until episode termination.

Architecture. We feed the last K timesteps into Decision Transformer, for a total of $3K$ tokens (one for each modality: return-to-go, state, or action). To obtain token embeddings, we learn a linear layer for each modality, which projects raw inputs to the embedding dimension, followed by layer normalization [15]. For environments with visual inputs, the state is fed into a convolutional encoder instead of a linear layer. Additionally, an embedding for each timestep is learned and added to each token – note this is different than the standard positional embedding used by transformers, as one timestep corresponds to three tokens. The tokens are then processed by a GPT [9] model, which predicts future action tokens via autoregressive modeling.

Training. We sample minibatches of sequence length K from the dataset. The prediction head corresponding to the input token s_t is trained to predict a_t – either with cross-entropy loss for discrete actions or mean-squared error for continuous actions – and the losses for each timestep are averaged. We did not find predicting the states or returns-to-go to improve performance, although it is possible (as shown in Section 5.4) and would be an interesting study for future work.

Algorithm 1 Decision Transformer Pseudocode (for continuous actions)

```
# R, s, a, t: returns-to-go, states, actions, or timesteps
# transformer: transformer with causal masking (GPT)
# embed_s, embed_a, embed_R: linear embedding layers
# embed_t: learned episode positional embedding
# pred_a: linear action prediction layer

# main model
def DecisionTransformer(R, s, a, t):
    # compute embeddings for tokens
    pos_embedding = embed_t(t) # per-timestep (note: not per-token)
    s_embedding = embed_s(s) + pos_embedding
    a_embedding = embed_a(a) + pos_embedding
    R_embedding = embed_R(R) + pos_embedding

    # interleave tokens as (R_1, s_1, a_1, ..., R_K, s_K)
    input_embs = stack(R_embedding, s_embedding, a_embedding)

    # use transformer to get hidden states
    hidden_states = transformer(input_embs=input_embs)

    # select hidden states for action prediction tokens
    a_hidden = unstack(hidden_states).actions

    # predict action
    return pred_a(a_hidden)

# training loop
for (R, s, a, t) in dataloader: # dims: (batch_size, K, dim)
    a_preds = DecisionTransformer(R, s, a, t)
    loss = mean((a_preds - a)**2) # L2 loss for continuous actions
    optimizer.zero_grad(); loss.backward(); optimizer.step()

# evaluation loop
target_return = 1 # for instance, expert-level return
R, s, a, t, done = [target_return], [env.reset()], [], [1], False
while not done: # autoregressive generation/sampling
    # sample next action
    action = DecisionTransformer(R, s, a, t)[-1] # for cts actions
    new_s, r, done, _ = env.step(action)

    # append new tokens to sequence
    R = R + [R[-1] - r] # decrement returns-to-go with reward
    s, a, t = s + [new_s], a + [action], t + [len(R)]
    R, s, a, t = R[-K:], ... # only keep context length of K
```

Figure 3: Results comparing Decision Transformer (ours) to TD learning (CQL) and behavior cloning across Atari, OpenAI Gym, and Minigrid. On a diverse set of tasks, Decision Transformer performs comparably or better than traditional approaches. Performance is measured by normalized episode return (see text for details).

4 Evaluations on Offline RL Benchmarks

In this section, we investigate if Decision Transformer can perform well compared to dedicated offline RL and imitation learning algorithms. In particular, our primary points of comparison are model-free offline RL algorithms based on TD-learning, since our Decision Transformer architecture is fundamentally model-free in nature as well. Furthermore, TD-learning is the dominant paradigm in RL for sample efficiency, and also features prominently as a sub-routine in many model-based RL algorithms [16, 17]. We also compare with behavior cloning and variants, since it also involves a likelihood based policy learning formulation similar to ours. The exact algorithms depend on the environment but our motivations are as follows:

- **TD learning:** most of these methods use an action-space constraint or value pessimism, and will be the most faithful comparison to Decision Transformer, representing standard RL methods. A state-of-the-art model-free method is Conservative Q-Learning (CQL) [14] which serves as our primary comparison. In addition, we also compare against other prior model-free RL algorithms like BEAR [18] and BRAC [19].
- **Imitation learning:** this regime similarly uses supervised losses for training, rather than Bellman backups. We use behavior cloning here, and include a more detailed discussion in Section 5.1.

We evaluate on both discrete (Atari [10]) and continuous (OpenAI Gym [11]) control tasks. The former involves high-dimensional observation spaces and requires long-term credit assignment, while the latter requires fine-grained continuous control, representing a diverse set of tasks. Our main results are summarized in Figure 3, where we show averaged normalized performance for each domain.

4.1 Atari

In this section, we consider Atari games [10], a widely-used RL benchmark. The Atari benchmark is challenging due to its high-dimensional visual inputs and difficulty of credit assignment arising from the delay between actions and resulting rewards. We evaluate our method on 1% of all samples in the DQN-replay dataset as per Agarwal et al. [13], representing 500 thousand of the 50 million transitions observed by an online DQN agent [20] during training; we report the mean and standard deviation of 3 seeds. We normalize scores based on a professional gamer, following the protocol of Hafner et al. [21], where 100 represents the professional gamer score and 0 represents a random policy.

We compare to CQL [14], REM [13], and QR-DQN [22] on four Atari tasks (Breakout, Qbert, Pong, and Seaquest) that are evaluated in Agarwal et al. [13]. We use context lengths of $K = 30$ for Decision Transformer (except $K = 50$ for Pong). We also report the performance of behavior cloning (BC), which utilizes the same network architecture and hyperparameters as Decision Transformer but does not have return-to-go conditioning². For CQL, REM, and QR-DQN baselines, we report numbers directly from the CQL paper. We show results in Table 1. Our method is competitive with CQL in 3 out of 4 games and outperforms or matches REM, QR-DQN, and BC on all 4 games.

²We also tried using an MLP with $K = 1$ as in prior work, but found this was worse than the transformer.

Game	DT (Ours)	CQL	QR-DQN	REM	BC
Breakout	267.5 \pm 97.5	211.1	21.1	32.1	138.9 \pm 61.7
Qbert	25.1 \pm 18.1	104.2	1.7	1.4	17.3 \pm 14.7
Pong	106.1 \pm 8.1	111.9	20.0	39.1	85.2 \pm 20.0
Seaquest	2.4 \pm 0.7	1.7	1.4	1.0	2.1 \pm 0.3

Table 1: Gamer-normalized scores for the 1% DQN-replay Atari dataset. We report the mean and variance across 3 seeds. Best mean scores are highlighted in bold. Decision Transformer (DT) performs comparably to CQL on 3 out of 4 games, and outperforms other baselines.

4.2 OpenAI Gym

In this section, we consider the continuous control tasks from the D4RL benchmark [23]. We also consider a 2D reacher environment that is not part of the benchmark, and generate the datasets using a similar methodology to the D4RL benchmark. Reacher is a goal-conditioned task and has sparse rewards, so it represents a different setting than the standard locomotion environments (HalfCheetah, Hopper, and Walker). The different dataset settings are described below.

1. Medium: 1 million timesteps generated by a “medium” policy that achieves approximately one-third the score of an expert policy.
2. Medium-Replay: the replay buffer of an agent trained to the performance of a medium policy (approximately 25k-400k timesteps in our environments).
3. Medium-Expert: 1 million timesteps generated by the medium policy concatenated with 1 million timesteps generated by an expert policy.

We compare to CQL [14], BEAR [18], BRAC [19], and AWR [24]. CQL represents the state-of-the-art in model-free offline RL, an instantiation of TD learning with value pessimism. Score are normalized so that 100 represents an expert policy, as per Fu et al. [23]. CQL numbers are reported from the original paper; BC numbers are run by us; and the other methods are reported from the D4RL paper. Our results are shown in Table 2. Decision Transformer achieves the highest scores in a majority of the tasks and is competitive with the state of the art in the remaining tasks.

Dataset	Environment	DT (Ours)	CQL	BEAR	BRAC-v	AWR	BC
Medium-Expert	HalfCheetah	86.8 \pm 1.3	62.4	53.4	41.9	52.7	59.9
Medium-Expert	Hopper	107.6 \pm 1.8	111.0	96.3	0.8	27.1	79.6
Medium-Expert	Walker	108.1 \pm 0.2	98.7	40.1	81.6	53.8	36.6
Medium-Expert	Reacher	89.1 \pm 1.3	30.6	-	-	-	73.3
Medium	HalfCheetah	42.6 \pm 0.1	44.4	41.7	46.3	37.4	43.1
Medium	Hopper	67.6 \pm 1.0	58.0	52.1	31.1	35.9	63.9
Medium	Walker	74.0 \pm 1.4	79.2	59.1	81.1	17.4	77.3
Medium	Reacher	51.2 \pm 3.4	26.0	-	-	-	48.9
Medium-Replay	HalfCheetah	36.6 \pm 0.8	46.2	38.6	47.7	40.3	4.3
Medium-Replay	Hopper	82.7 \pm 7.0	48.6	33.7	0.6	28.4	27.6
Medium-Replay	Walker	66.6 \pm 3.0	26.7	19.2	0.9	15.5	36.9
Medium-Replay	Reacher	18.0 \pm 2.4	19.0	-	-	-	5.4
Average (Without Reacher)		74.7	63.9	48.2	36.9	34.3	46.4
Average (All Settings)		69.2	54.2	-	-	-	47.7

Table 2: Results for D4RL datasets³. We report the mean and variance for three seeds. Decision Transformer (DT) outperforms conventional RL algorithms on almost all tasks.

³Given that CQL is generally the strongest TD learning method, for Reacher we only run the CQL baseline.

5 Discussion

5.1 Does Decision Transformer perform behavior cloning on a subset of the data?

In this section, we seek to gain insight into whether Decision Transformer can be thought of as performing imitation learning on a subset of the data with a certain return. To investigate this, we propose a new method, Percentile Behavior Cloning (%BC), where we run behavior cloning on only the top $X\%$ of timesteps in the dataset, ordered by episode returns. The percentile $X\%$ interpolates between standard BC ($X = 100\%$) that trains on the entire dataset and only cloning the best observed trajectory ($X \rightarrow 0\%$), trading off between better generalization by training on more data with training a specialized model that focuses on a desirable subset of the data.

We show full results comparing %BC to Decision Transformer and CQL in Table 3, sweeping over $X \in [10\%, 25\%, 40\%, 100\%]$. Note that the only way to choose the optimal subset for cloning is to evaluate using rollouts from the environment, so %BC is not a realistic approach; rather, it serves to provide insight into the behavior of Decision Transformer. When data is plentiful – as in the D4RL regime – we find %BC can match or beat other offline RL methods. On most environments, Decision Transformer is competitive with the performance of the best %BC, indicating it can hone in on a particular subset after training on the entire dataset distribution.

Dataset	Environment	DT (Ours)	10%BC	25%BC	40%BC	100%BC	CQL
Medium	HalfCheetah	42.6 ± 0.1	42.9	43.0	43.1	43.1	44.4
Medium	Hopper	67.6 ± 1.0	65.9	65.2	65.3	63.9	58.0
Medium	Walker	74.0 ± 1.4	78.8	80.9	78.8	77.3	79.2
Medium	Reacher	51.2 ± 3.4	51.0	48.9	58.2	58.4	26.0
Medium-Replay	HalfCheetah	36.6 ± 0.8	40.8	40.9	41.1	4.3	46.2
Medium-Replay	Hopper	82.7 ± 7.0	70.6	58.6	31.0	27.6	48.6
Medium-Replay	Walker	66.6 ± 3.0	70.4	67.8	67.2	36.9	26.7
Medium-Replay	Reacher	18.0 ± 2.4	33.1	16.2	10.7	5.4	19.0
Average		56.1	56.7	52.7	49.4	39.5	43.5

Table 3: Comparison between Decision Transformer (DT) and Percentile Behavior Cloning (%BC).

In contrast, when we study low data regimes – such as Atari, where we use 1% of a replay buffer as the dataset – %BC is weak (shown in Table 4). This suggests that in scenarios with relatively low amounts of data, Decision Transformer can outperform %BC by using all trajectories in the dataset to improve generalization, even if those trajectories are dissimilar from the return conditioning target. Our results indicate that Decision Transformer can be more effective than simply performing imitation learning on a subset of the dataset. On the tasks we considered, Decision Transformer either outperforms or is competitive to %BC, without the confound of having to select the optimal subset.

Game	DT (Ours)	10%BC	25%BC	40%BC	100%BC
Breakout	267.5 ± 97.5	28.5 ± 8.2	73.5 ± 6.4	108.2 ± 67.5	138.9 ± 61.7
Qbert	25.1 ± 18.1	6.6 ± 1.7	16.0 ± 13.8	11.8 ± 5.8	17.3 ± 14.7
Pong	106.1 ± 8.1	2.5 ± 0.2	13.3 ± 2.7	72.7 ± 13.3	85.2 ± 20.0
Seaquest	2.4 ± 0.7	1.1 ± 0.2	1.1 ± 0.2	1.6 ± 0.4	2.1 ± 0.3

Table 4: %BC scores for Atari. We report the mean and variance across 3 seeds. Decision Transformer (DT) outperforms all versions of %BC.

5.2 How well does Decision Transformer model the distribution of returns?

We evaluate the ability of Decision Transformer to understand return-to-go tokens by varying the desired target return over a wide range – evaluating the multi-task distribution modeling capability of transformers. Figure 4 shows the average sampled return accumulated by the agent over the course of the evaluation episode for varying values of target return. On every task, the desired target returns and the true observed returns are highly correlated. On some tasks like Pong, HalfCheetah and Walker, Decision Transformer generates trajectories that almost perfectly match the desired returns

(as indicated by the overlap with the oracle line). Furthermore, on some Atari tasks like Seaquest, we can prompt the Decision Transformer with higher returns than the maximum episode return available in the dataset, demonstrating that Decision Transformer is sometimes capable of extrapolation.

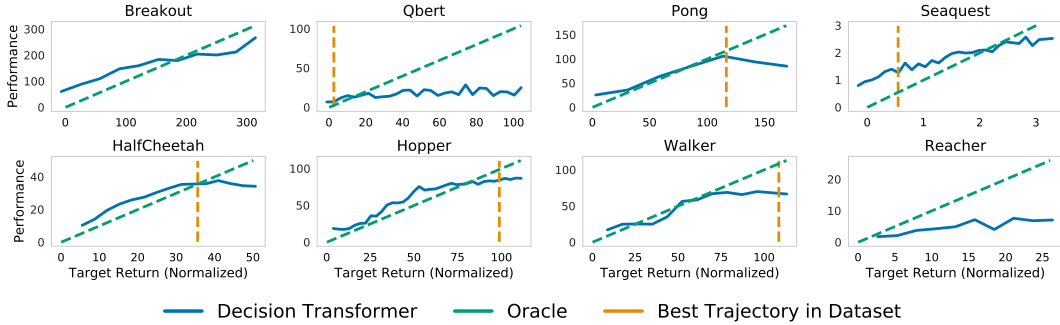

Figure 4: Sampled (evaluation) returns accumulated by Decision Transformer when conditioned on the specified target (desired) returns. **Top:** Atari. **Bottom:** D4RL medium-replay datasets.

5.3 What is the benefit of using a longer context length?

To assess the importance of access to previous states, actions, and returns, we ablate on the context length K . This is interesting since it is generally considered that the previous state (i.e. $K = 1$) is enough for reinforcement learning algorithms when frame stacking is used, as we do. Table 5 shows that performance of Decision Transformer is significantly worse when $K = 1$, indicating that past information is useful for Atari games. One hypothesis is that when we are representing a distribution of policies – like with sequence modeling – the context allows the transformer to identify *which* policy generated the actions, enabling better learning and/or improving the training dynamics.

Game	DT (Ours)	DT with no context ($K = 1$)
Breakout	267.5 ± 97.5	73.9 ± 10
Qbert	25.1 ± 18.1	13.7 ± 6.5
Pong	106.1 ± 8.1	2.5 ± 0.2
Seaquest	2.4 ± 0.7	0.5 ± 0.0

Table 5: Ablation on context length. Decision Transformer (DT) performs better when using a longer context length ($K = 50$ for Pong, $K = 30$ for others).

5.4 Does Decision Transformer perform effective long-term credit assignment?

To evaluate long-term credit assignment capabilities of our model, we consider a variant of the Key-to-Door environment proposed in Mesnard et al. [12]. This is a grid-based environment with a sequence of three phases: (1) in the first phase, the agent is placed in a room with a key; (2) then, the agent is placed in an empty room; (3) and finally, the agent is placed in a room with a door. The agent receives a binary reward when reaching the door in the third phase, but **only** if it picked up the key in the first phase. We train on datasets of trajectories generated by applying random actions and report success rates in Table 6. Methods that use hindsight return information: our Decision Transformer model and %BC (trained only on successful episodes) are able to learn effective policies – producing near-optimal paths, despite only training on random walks. TD learning (CQL) cannot effectively propagate Q-values over the long horizons involved and gets poor performance.

Dataset	DT (Ours)	CQL	BC	%BC	Random
1K Random Trajectories	71.8%	13.1%	1.4%	69.9%	3.1%
10K Random Trajectories	94.6%	13.3%	1.6%	95.1%	3.1%

Table 6: Success rate for Key-to-Door environment. Methods using hindsight (Decision Transformer, %BC) can learn successful policies, while TD learning struggles to perform credit assignment.

5.5 Can transformers be accurate critics in sparse reward settings?

In previous sections, we established that decision transformer can produce effective policies (actors). We now evaluate whether transformer models can also be effective critics. We modify Decision Transformer to output return tokens in addition to action tokens on the Key-to-Door environment. We find that the transformer continuously updates reward probability based on events during the episode, shown in Figure 5 (Left). Furthermore, we find the transformer attends to critical events in the episode (picking up the key or reaching the door), shown in Figure 5 (Right), indicating formation of state-reward associations as discussed in Raposo et al. [25] and enabling accurate value prediction.

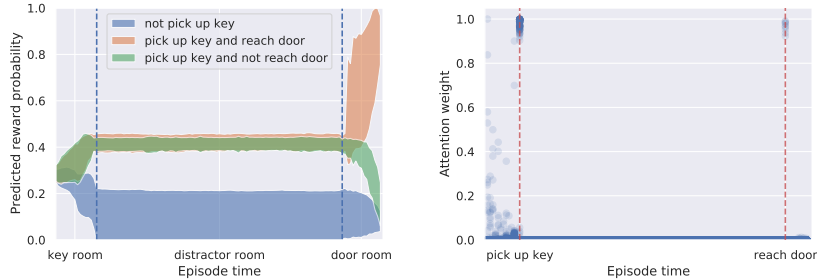

Figure 5: **Left:** Averages of running return probabilities predicted by the transformer model for three types of episode outcomes. **Right:** Transformer attention weights from all timesteps superimposed for a particular successful episode. The model attends to steps near pivotal events in the episode, such as picking up the key and reaching the door.

5.6 Does Decision Transformer perform well in sparse reward settings?

A known weakness of TD learning algorithms is that they require densely populated rewards in order to perform well, which can be unrealistic and/or expensive. In contrast, Decision Transformer can improve robustness in these settings since it makes minimal assumptions on the density of the reward. To evaluate this, we consider a delayed return version of the D4RL benchmarks where the agent does not receive any rewards along the trajectory, and instead receives the cumulative reward of the trajectory in the final timestep. Our results for delayed returns are shown in Table 7. Delayed returns minimally affect Decision Transformer; and due to the nature of the training process, while imitation learning methods are reward agnostic. While TD learning collapses, Decision Transformer and %BC still perform well, indicating that Decision Transformer can be more robust to delayed rewards.

Dataset	Environment	Delayed (Sparse)		Agnostic		Original (Dense)	
		DT (Ours)	CQL	BC	%BC	DT (Ours)	CQL
Medium-Expert	Hopper	107.3 ± 3.5	9.0	59.9	102.6	107.6	111.0
Medium	Hopper	60.7 ± 4.5	5.2	63.9	65.9	67.6	58.0
Medium-Replay	Hopper	78.5 ± 3.7	2.0	27.6	70.6	82.7	48.6

Table 7: Results for D4RL datasets with delayed (sparse) reward. Decision Transformer (DT) and imitation learning are minimally affected by the removal of dense rewards, while CQL fails.

5.7 Why does Decision Transformer avoid the need for value pessimism or behavior regularization?

One key difference between Decision Transformer and prior offline RL algorithms is that we do not require policy regularization or conservatism to achieve good performance. Our conjecture is that TD-learning based algorithms learn an approximate value function and improve the policy by optimizing this value function. This act of optimizing a learned function can exacerbate and exploit any inaccuracies in the value function approximation, causing failures in policy improvement. Since Decision Transformer does not require explicit optimization using learned functions as objectives, it avoids the need for regularization or conservatism.

5.8 How can Decision Transformer benefit online RL regimes?

Offline RL and the ability to model behaviors has the potential to enable sample-efficient online RL for downstream tasks. Works studying the transition from offline to online generally find that likelihood-based approaches, like our sequence modeling objective, are more successful [26, 27]. As a result, although we studied offline RL in this work, we believe Decision Transformer can meaningfully improve online RL methods by serving as a strong model for behavior generation. For instance, Decision Transformer can serve as a powerful “memorization engine” and in conjunction with powerful exploration algorithms like Go-Explore [28], has the potential to simultaneously model and generate a diverse set of behaviors.

6 Related Work

6.1 Offline and supervised reinforcement learning

To mitigate the impact of distribution shift in offline RL, prior algorithms either (a) constrain the policy action space [29, 30, 31] or (b) incorporate value pessimism [29, 14], or (c) incorporate pessimism into learned dynamics models [32, 33]. Since we do not use Decision Transformers to explicitly learn the dynamics model, we primarily compare against model-free algorithms in our work. Another line of work explores learning wide behavior distribution from an offline dataset by learning a task-agnostic set of skills, either with likelihood-based approaches [34, 35, 36, 37] or by maximizing mutual information [38, 39, 40]. Our work is similar to the likelihood-based approaches, although we use a simpler sequence modeling objective instead of a variational method, and use rewards for conditional generation of behaviors. Furthermore, other works have proposed return conditioning/“supervised RL” methods: Kumar et al. [41] and Srivastava et al. [42] train Markovian agents with a supervised loss to predict actions conditioned on episode returns for online RL. While these methods are similar to ours, Decision Transformers benefit from the use of long contexts for behavior modeling as long-term credit assignment.

6.2 Credit assignment

Many works have studied better credit assignment via state-association, learning an architecture which decomposes the reward function such that certain “important” states comprise most of the credit [43, 44, 12]. They use the learned reward function to change the reward of an actor-critic algorithm to help propagate signal over long horizons. In particular, similar to our long-term setting, some works have specifically shown such state-associative architectures can perform better in delayed reward settings [45, 7, 46, 25]. In contrast, we allow these properties to naturally emerge in a transformer architecture, without having to explicitly learn a reward function or a critic.

6.3 Conditional language generation

Various works have studied guided generation for images [47] and language [48, 49]. Several works [50, 51, 52, 53, 54, 55] have explored training or fine-tuning of models for controllable text generation. Class-conditional language models can also be used to learn discriminators to guide generation [56, 48, 57, 58]. However, these approaches mostly assume constant “classes”, while in reinforcement learning the reward signal is time-varying. Furthermore, it is more natural to prompt the model desired target return and continuously decrease it by the observed rewards over time, since the transformer model and environment jointly generate the trajectory.

6.4 Attention and transformer models

Transformers [1] have been applied successfully to many tasks in natural language processing [59, 9] and computer vision [60, 61]. However, transformers are relatively unstudied in RL, mostly due to differing nature of the problem, such as higher variance in training. Zambaldi et al. [5] showed that augmenting transformers with relational reasoning improve performance in combinatorial environments and Ritter et al. [62] showed iterative self-attention allowed for RL agents to better utilize episodic memories. Parisotto et al. [4] discussed design decisions for more stable training of transformers in the high-variance RL setting. Unlike our work, these still use actor-critic algorithms for optimization, focusing on novelty in architecture. Additionally, in imitation learning, some

works have studied transformers as a replacement for LSTMs: Dasari and Gupta [63] study one-shot imitation learning, and Abramson et al. [64] combine language and image modalities.

7 Conclusion

We proposed Decision Transformer, seeking to unify ideas in language/sequence modeling and reinforcement learning. On standard offline RL benchmarks, we showed Decision Transformer can match or outperform strong algorithms designed explicitly for offline RL with minimal modifications from standard language modeling architectures.

We hope this work inspires more investigation into using large transformer models for RL. We used a simple supervised loss that was effective in our experiments, but applications to large-scale datasets could benefit from self-supervised pretraining tasks. In addition, one could consider more sophisticated embeddings for returns, states, and actions – for instance, conditioning on return distributions to model stochastic settings instead of deterministic returns. Transformer models can also be used to model the state evolution of trajectory, potentially serving as an alternative to model-based RL, and we hope to explore this in future work.

For real-world applications, it is important to understand the types of errors transformers make in MDP settings and possible negative consequences, which are underexplored. It will also be important to consider the datasets we train models on, which can potentially add destructive biases, particularly as we consider studying augmenting RL agents with more data which may come from questionable sources. For instance, reward design by nefarious actors can potentially generate unintended behaviors as our model generates behaviors by conditioning on desired returns.

Acknowledgements

This research was supported by Berkeley Deep Drive, Open Philanthropy, and the National Science Foundation under NSF:NRI #2024675. Part of this work was completed when Aravind Rajeswaran was a PhD student at the University of Washington, where he was supported by the J.P. Morgan PhD Fellowship in AI (2020-21). We also thank Luke Metz and Daniel Freeman for valuable feedback and discussions, as well as Justin Fu for assistance in setting up D4RL benchmarks.

A Experimental Details

Code for experiments can be found at: <https://github.com/kzl/decision-transformer>.

A.1 Atari

We build our Decision Transformer implementation for Atari games off of minGPT (<https://github.com/karpathy/minGPT>), a publicly available re-implementation of GPT. We use most of the default hyperparameters from their character-level GPT example (https://github.com/karpathy/minGPT/blob/master/play_char.ipynb). We reduce the batch size (except in Pong), block size, number of layers, attention heads, and embedding dimension for faster training. For processing the observations, we use the DQN encoder from Mnih et al. [20] with an additional linear layer to project to the embedding dimension.

For return-to-go conditioning, we use either $1\times$ or $1.5\times$ CQL performance. We selected these values as our primary focus was comparison to CQL, but more possibilities exist for principled return-to-go conditioning. In Atari experiments, we use Tanh instead of LayerNorm (as described in Section 3) after embedding each modality, but did this does not make a significant difference in performance. The full list of hyperparameters can be found in Table 8.

Table 8: Hyperparameters of DT (and %BC) for Atari experiments.

Hyperparameter	Value
Number of layers	6
Number of attention heads	8
Embedding dimension	128
Batch size	512 Pong 128 Breakout, Qbert, Seaquest
Context length K	50 Pong 30 Breakout, Qbert, Seaquest
Return-to-go conditioning	90 Breakout ($\approx 1.5\times$ CQL performance) 14000 Qbert ($\approx 1\times$ CQL performance) 20 Pong ($\approx 1\times$ CQL performance) 1150 Seaquest ($\approx 1.5\times$ CQL performance)
Nonlinearity	ReLU, encoder GeLU, otherwise
Encoder channels	32, 64, 64
Encoder filter sizes	$8\times 8, 4\times 4, 3\times 3$
Encoder strides	4, 2, 1
Max epochs	5
Dropout	0.1
Learning rate	6×10^{-4}
Adam betas	(0.9, 0.95)
Grad norm clip	1.0
Weight decay	0.1
Learning rate decay	Linear warmup and cosine decay (see code for details)
Warmup tokens	512×20
Final tokens	$2\times 500000\times K$

A.2 OpenAI Gym

A.2.1 Decision Transformer

Our code is based on the Huggingface Transformers library [65]. Our hyperparameters on all OpenAI Gym tasks are shown below in Table 9. Heuristically, we find using larger models helps to model the distribution of returns, compared to standard RL model sizes (which learn one policy). For reacher we use a smaller context length than the other environments, which we find to be helpful as the environment is goal-conditioned and the episodes are shorter. We choose return targets based on expert performance for each environment, except for HalfCheetah where we find 50% performance

to be better due to the datasets containing lower relative returns to the other environments. Models were trained for 10^5 gradient steps using the AdamW optimizer [66] following PyTorch defaults.

Table 9: Hyperparameters of Decision Transformer for OpenAI Gym experiments.

Hyperparameter	Value
Number of layers	3
Number of attention heads	1
Embedding dimension	128
Nonlinearity function	ReLU
Batch size	64
Context length K	20 HalfCheetah, Hopper, Walker 5 Reacher
Return-to-go conditioning	6000 HalfCheetah 3600 Hopper 5000 Walker 50 Reacher
Dropout	0.1
Learning rate	10^{-4}
Grad norm clip	0.25
Weight decay	10^{-4}
Learning rate decay	Linear warmup for first 10^5 training steps

A.2.2 Behavior Cloning

As briefly mentioned in Section 4.2, we found previously reported behavior cloning baselines to be weak, and so run them ourselves using a similar setup as Decision Transformer. We tried using a transformer architecture, but found using an MLP (as in previous work) to be stronger. We train for 2.5×10^4 gradient steps; training more did not improve performance. Other hyperparameters are shown in Table 10. The percentile behavior cloning experiments use the same hyperparameters.

Table 10: Hyperparameters of Behavior Cloning for OpenAI Gym experiments.

Hyperparameter	Value
Number of layers	3
Embedding dimension	256
Nonlinearity function	ReLU
Batch size	64
Dropout	0.1
Learning rate	10^{-4}
Weight decay	10^{-4}
Learning rate decay	Linear warmup for first 10^5 training steps

B Atari Task Scores

Table 11 shows the normalized scores used for normalization used in Hafner et al. [21]. Tables 12 and 13 show the raw scores corresponding to Tables 1 and 4, respectively. For %BC scores, we use the same hyperparameters as Decision Transformer for fair comparison.

Game	Random	Gamer
Breakout	2	30
Qbert	164	13455
Pong	-21	15
Seaquest	68	42055

Table 11: Atari baseline scores used for normalization.

Game	DT (Ours)	CQL	QR-DQN	REM	BC
Breakout	76.9 \pm 27.3	61.1	7.9	11.0	40.9 \pm 17.3
Qbert	3498.3 \pm 2402.1	14012.0	383.6	343.4	2464.1 \pm 1948.2
Pong	17.1 \pm 2.9	19.3	-13.8	-6.9	9.7 \pm 7.2
Seaquest	1063.3 \pm 274.8	779.4	672.9	499.8	968.6 \pm 133.8

Table 12: Raw scores for the 1% DQN-replay Atari dataset. We report the mean and variance across 3 seeds. Best mean scores are highlighted in bold. Decision Transformer (DT) performs comparably to CQL on 3 out of 4 games, and outperforms other baselines.

Game	DT (Ours)	10%BC	25%BC	40%BC	100%BC
Breakout	76.9 \pm 27.3	10.0 \pm 2.3	22.6 \pm 1.8	32.3 \pm 18.9	40.9 \pm 17.3
Qbert	3498.3 \pm 2402.1	1045 \pm 232.0	2302.5 \pm 1844.1	1674.1 \pm 776.0	2464.1 \pm 1948.2
Pong	17.1 \pm 2.9	-20.3 \pm 0.1	-16.2 \pm 1.0	5.2 \pm 4.8	9.7 \pm 7.2
Seaquest	1063.3 \pm 274.8	521.3 \pm 103.0	549.3 \pm 96.2	758 \pm 169.1	968.6 \pm 133.8

Table 13: %BC scores for Atari. We report the mean and variance across 3 seeds. Decision Transformer (DT) outperforms all versions of %BC.
